ABSTRACT

Graft copolymers of natural polysaccharides chitosan (Chs), gummi-arabic (GA) and arabinogalactan (AG) were synthesized with N-vinylpyrrolidone (VP) (4-vinylpyridine and N-vinylpyrrolidone used as comonomers for chitosan grafting), and then pH-sensitive hydrogels were designed by cross-linked them with N,N-methylene-bis-acrylamide. Effective sorption of doxycycline from aqueous solutions with water-swelling gels has been studied experimentally. The effect of gel dose, initial concentration of doxycycline, pH medium and solution ionic strength of the sorption rate and capacity of the antibiotic was systematically studied. The surface and volume absorption kinetics and isotherms of the process have also been investigated. It was found that the max sorption capacity for swellable gels varies between Chs-graft-VP/4VP>AG/graft-VP>GA/graft-VP. It has been shown that the sorption mechanism is mainly dominated by physical sorption and to some extent hydrogen bonds and electrostatic interactions.

Keywords: Chitosan, Gummiarabic, Arabivogalactan, Graft copolymer, Hydrogel, Doxycycline, Sorption.

INTRODUCTION

It is known that antibiotics are widely used in modern medicine in the treatment of inflammatory diseases, destruction or inhibition of bacterial cells¹,². Doxycycline (Dox) is one of the anthracycline series of antibiotics which is currently used in inflammatory diseases of the respiratory and gastrointestinal tract³-⁵. Dox is a broad-spectrum antibacterial drug consisting of free -OH, -NH₂, and carbonyl groups. Doxycycline is a semi-crystalline antibiotic and is used to treat superficial diseases of the eye, periodic epithelial erosion, and corneal wounds⁶-⁸. Sorption of antibiotics by ion exchange materials is widely used in their separation and purification processes. There is also some scientific research in the periodical literature on the sorption of antibiotics by polymer sorbents and the study of thermodynamics and kinetics of the process⁹,¹⁰. The inclusion of drugs in polysaccharide macromolecules not only reduces their adverse effects on the body,
but also increases their bioavailabilities.

In addition, some drugs pollute the environment after use, which has a detrimental effect on humans, animals and plants\(^{(11,12)}\). It is known that this antibiotic is not fully absorbed and 30-90% of the dose is excreted without biological activity\(^{(14)}\). Separation of Dox from polluting water to prevent such adverse effects is an actual topic. Research on its adsorption of Dox on organic, inorganic and hybrid polymeric materials can be found in the literature\(^{(15-20)}\).

From this point of view, the effective removal of Dox with natural polymer-based hydrogels is an urgent problem. The synthesis of new types of hydrogel materials is of great interest. In the literature, sorption of Dox with Chs, GA and AG-based hydrogels is highly preferred. Because these polymers have great potential in the industry and we can briefly mention the following about them. AG is a hyperbranched natural polysaccharide which has gasprotector, membrane-conducting and high sorption capacity properties. It is widely used as a carrier of enzymes, drugs and essential minerals for the human body. The AG macromolecule has a highly branched structure (Fig. 2): the main chain consists of a galactose chain connected by a $\beta-(1\rightarrow3)$ glucoside bond. The side chain is composed of uronic acids, mainly glucuronic acids, which bind to the galactose and arabinose links by a $\beta-(1\rightarrow6)$ bond\(^{(21-24)}\).

Chs is a polycationite type natural linear structural polyaminosaccharide obtained from chitin by deacetylation process. Chitosan is composed of randomly distributed $\beta$-(1,4)-2-amino-2-deoxy-glucosamine and $\beta$-(1,4)-N-acetyl glucosamine units\(^{(25-27)}\). The high sorption capacity due to metal ions, non-toxicity, and drugs, and easily chemical functional of Chs macromolecules confirm that its perfect chemical and physical properties in delivery of biological active compounds in biotechnology and stabilization of antibacterial metal nanoparticles\(^{(28-31)}\).

GA, a natural polysaccharide, is a biologically inert polymer used in medicine to make soft and hard capsules and to make high sorption adsorbents. The GA macromolecule has a hyper branch chemical structure (Fig. 2). Its elemental link consists of pentose, methyl pentose, hexose and polyuronic acid units combined with each other\(^{(32,33)}\). The main skeleton of the GA macromolecule is composed of galactose and mannose, and the side branches are composed of pentose and xylose units. In the present study, pH-sensitive gels were synthesized from the cross-linking of Chs VPr and 4VP graft copolymer with glutaraldehyde, and GA and AG VPr graft copolymer cross-linked with MBAA. The structural characteristics of the gels were studied and the sorption isotherms of doxycycline were investigated. The parameters of antibiotic separation from the aqueous solution were also determined and the sorption results were applied in different kinetic models.

**EXPERIMENTAL**

ChS (deacetylation degree and average molecular weight are 87-90% and 35 kDa, respectively), AG and GA were obtained from Sigma Aldrich (AG, 200 kDa; GA 400 kDa). Glacial acetate acid, acetone ($\geq99.8\%$), ethanol (95%), diethyl ether ($\geq99.6\%$) and MBAA also from Sigma-Aldrich co ltd. As initiator used 2,2-azobisisobutyronitrile (AIBN) and 4VP (assay 95-96%), VPr ($\geq99.8\%$) and MBA also from Sigma-Aldrich co ltd. As initiator used 2,2-azobisisobutyronitrile (AIBN) and 4VP (assay 95-96%), VPr ($\geq99.8\%$) were also purchased from Acros Organics and had been distilled and recrystallization before the use. All solvents were purified by distillation, according to the conventional methods and were purchased from Sigma Aldrich. Dox with the empiric chemical formula $\text{C}_{22}\text{H}_{24}\text{N}_{2}\text{O}_{8}\times\text{HCl}\times0.5\text{H}_{2}\text{O}$ was obtained from Merck.

**Gel preparation**

ChS (AG or GA) is dried at 40-50°C (24 h) suspended by 150 mL of 2% $\text{CH}_3\text{COOH}$, then 1-2 h mixing. 2 mL monomer’s - VPr and 4VP (1:1 mol ratio) were added to the Chs solution and continuously stirred in 30 min (VPr only for AG and GA). The reaction was performed according to the method\(^{(21)}\). Graft-natural polysaccharides (graft-Np) copolymer samples are mixed with a cross-linking reagent and gelation obtained within 30 min (65-75°C). Prepared all three natural based hydrogels were washed with bidistilled water and ethanol, respectively\(^{(21)}\).
Characterizations
The infrared properties of the Chs, AG and GA graft copolymer based hydrogel and hydrogels-Dox simples were analysis by Fourier transforms infrared spectrophotometer (FTIR) in the 4000–400 cm\(^{-1}\) range by Nicolet 6700, (USA) instrument. Nanosized Zetasizer ZS90, Mulvern instrument used for measurements of surface zeta potential of obtained hydrogels. The initial and equilibrium concentrations of Dox in aqueous solution were determined by an ultraviolet spectrophotometer at 349 nm (UV-Vis 2550, Shimadzu, Japan).

Adsorption experiments
The doxycycline removal experiments for the three different hydrogel samples were conducted with a 90 mg/L initial concentration\(^{16}\). Ten mL of the antibiotics solution was mixed with natural based hydrogel (4 mg) at different pH, removal times, and temperatures. The samples were filtered with specific filters from Millipore prior. The calibration curves of various antibiotics concentrations were established from 10; 20; 40; 60 and 90 mg/L concentrations with best linearity in all circumstances.

Adsorption isotherms for the all hydrogel simples performed the following method. Ten mL solutions of the neutral pH antibiotics solution with different concentrations (10, 20, 40, 60 and 90 mg/L) were mixed and stirred at 20\(^\circ\)C temperature with the hydrogel graft-Np (4 mg) at different contact times for Dox antibiotic. Equilibrium condition determination experimentally, for the Dox adsorption according to the method\(^{34}\). Concentrations of antibiotics were determined as described above due to the method. Adsorption capacity of graft-Np, \(Q_e\), was calculated according to Eq.1:

\[
Q_e = \frac{(C_0 - C_e) \times V}{m}
\]  

(1)

Where, \(Q_e\) is the equilibrium Dox sorption capacity (mg/gr), \(C_0\) is initial and \(C_e\) is the equilibrium concentrations of antibiotics (mg/L), \(V=10\) mL is the volume of Dox solutions, and \(m\) is of the graft-Np dose by mg.

RESULT AND DISCUSSION
In a previous study\(^{21}\) author obtained the optimal graft co-polymer reaction condition of radical copolymerization of VPr and 4VP into ChS macromolecule. For this graft co-polymers synthesis, MBAA as a specific cross-linker was prepared. The new pH sensitive hydrogels could form after chemical binding of graft-ChS-PVPr-co-P4VP simples with MBAA by radical reaction. This covalent binding occurred between \(-\text{CH}_2\) groups of PVPr, \(-\text{NH}_2\) groups of ChS and \(-\text{CH}<\) groups on P4PV. A possible radical chemical reaction mechanism of co-grafting could be shown in Fig. 1 by the author\(^{34}\).
Additional, the FTIR spectra of GA and AG for the adsorption of Dox typical chemical peaks of polymer chains observed in different regions. In 3430 cm\(^{-1}\) peak concerning aromatic connected O–H, 1620 cm\(^{-1}\) of benzene ring C=C bonds, 1390 cm\(^{-1}\) to –COO–, and 1090 cm\(^{-1}\) intensive peak belongs to C–O–C bonds. After the adsorption of Dox, the peaks at 400–800 cm\(^{-1}\) interval belonged to the aromatic –CH chemical group of antibiotics, proposed that the antibiotic molecule was adsorbed onto the hydrogel surface layer. The peak shifted from 3430 cm\(^{-1}\) to 3440 cm\(^{-1}\) belongs to O-H, the peaks shifted from 1390 to 1430 cm\(^{-1}\) belongs of –COO– and the peaks shifted from 1090 cm\(^{-1}\) to 1100 cm\(^{-1}\) belongs to alkoxy C–O–C bonds after adsorption of Dox molecules. The double of C=C bonds peaks about to the aromatic group shifted from 1622 to 1631 cm\(^{-1}\) region after complexes of the Dox, show that the p-p electron-donor acceptor chemical force between Dox molecules and hydrogels was proposed as the important parameter for drug adsorption\(^{40,41}\).

The effect of pH of the medium and dose of gel simple on Dox removal was studied in detail (Figure 3).

Shown that, the removal efficiency of Dox depends on from the solution pH, initially increased and then began decreased. Graft-Nps exhibited higher antibiotic capacity at neutral pH. According to the sorption result, the adsorption of Dox was highly pH-dependent, and the cross-linking chains of the hydrogels played an important role in antibiotic sorption. The medium of the pH affected the hydrogel top layer charge and also the Dox dispensation in solution. It is clear that, graft-Nps carried various O-containing –COOH and hydroxyl functional groups. Most of these chemical functional groups are positively charged due to the protonated acidic pH medium. The hydrogel surface’s chemical functional groups will become the deprotonation and negatively charged at higher pH.
It’s known that Dox has multiple –OH, -C₆H₄-OH, -NH₂ ionisable chemical functional groups hence can exist as a cation, anion and a zwitterion. This also makes it possess multiple values for pKa (acid dissociation constant). Between intermediate pH values it exists as a zwitterion. When the pKa1=3.02 at pH<3.02 Dox exists as a Dox⁺. When pK_a2=7.97 at 3.02<pH<7.97 medium antibiotic exists as a Dox⁻. Between pH 7.97 and 9.15 it exists as Dox⁻ and pK_a3=9.15 and also pH>9.15 due to the –C₆H₄-CO-O- moiety and tri-C=O system loss of protons antibiotic as an Dox²⁻. The three different ionisable forms of Dox functional groups are shown in Figure 4.

![Fig. 4. The positions of different ionisable chemical functional groups of Dox chemical structure at different pK_a.](image)

The main form of Dox molecules would be zwitter-ionic and cationic types at pH≤7, and this form is effectively available for p→p electro-donor acceptor chemical interaction. This interaction formed with the pyridine ring structures of the Chs based hydrogel. When the pH values increase, Dox molecules begin to deprotonation and results decrease the π-withdrawing ability of the group. In addition, the electrostatic repulsion between the anionic form of Dox molecules and the functional groups deprotonated of natural based hydrogels increased with increasing pH values. At the end this leads to a decrease in sorption capacity.

The effect of Na⁺ and Cl⁻ ions and non-electrolyte concentration on the sorption of Dox by hydrogel samples is shown in Figurs 5.

![Fig. 5. The effects of NaCl and glucose concentration of Dox sorption by Chs-graft-VPr/4VP, AG-graft-VPr and GA-graft-VPr based hydrogel sorbents. C_Dox = 40 mg/L; hydrogel dose = 40 mg; T = 298 K; contact time = 24 hours.](image)

As can be seen, the antibiotic capacity of the AG and GA-based gel sorbents decreases as the concentration of NaCl in the solution increases. In Chs based gel, the antibiotic capacity increases to a concentration of 4 mg/L and then begins to decrease. However, the effect of electrolyte concentration on Dox sorption by Chs based gel is not so sharp. It seems that the interaction between the antibiotic molecule and the gel is stronger, and the concentration of Na⁺ and Cl⁻ ions up to 10 mg/L has little effect on the weakening of these interactions. Such a strong interaction is due to the presence of a pyridine ring in the structure. Which proves the existence of the interaction π→π in this system. In AG and GA-based gel samples, the antibiotic capacity of the gel begins to decrease by more than 20% as the electrolyte concentration increases. Because in this case, the chemical bond does not occur, as in Chs.
Where $C_e$ is the concentration of Dox in equilibrium condition, mg/L, $Q_e$ is the amount of Dox adsorbed per gram of natural based hydrogel $\text{graft-Np}$ at equilibrium condition, mg/gr, $Q_m$ is the maximum adsorption capacity which is calculated by theoretical by $\text{graft-Np}$ for Dox, mg/gr, $K_L$ is a constant of Langmuir isotherm, l/mg, $K_F$ is the empirical constant for Freundlich adsorption isotherm of the $\text{graft-Np}$, and $1/n$ is a the Freundlich adsorption constant.

The adsorption data of the studied Dox molecules onto $\text{graft-Nps}$ were fitted with the Langmuir and Freundlich isotherms (Fig. 6). These two models, which can provide information on the 2 important parameters: adsorption capacity and affinity. The adsorption of Dox happened in a homogeneous surface of the natural based hydrogels according to the Langmuir model. But according to the Freundlich model the adsorption is not reversible, occurring by formation of multilayers of $\text{graft-Nps}$ on a hydrogel surface. The Freundlich model the best fitted for the adsorption process by $\text{Chs}$ and $\text{AG-graft}$ polymers based gel according to the $R^2$ correlation coefficient (Table 1). But Dox sorption data is best fitted with the Langmuir and Freundlich models for the GA based graft copolymer gel.

The $1/n$ values of the constant were less than 1 due to the Freundlich model, and this indicated suitable adsorption process (Table 1). The $Q_m$ highest adsorption capacity for the $\text{Chs}$ based graft copolymer, which was found to follow the physical-sorption mechanism adsorption of Dox. According to $R_L = 1/(1 + K_L C_0)$ equation Langmuir constant $K_L$ can be calculated and presented in Table 1. The dimensionless separation factors calculated for $\text{Chs}$ graft copolymer based gel is 0.006. The values of $R_L$ for $\text{AG}$ and $\text{GA}$ based copolymer gels are 0.019 and 0.029, respectively. If the $R_L$ datas were greater than zero and less than 1, these results showed favorable adsorption.

Forming stable adsorption and an effective system requires full understanding of the dynamic process of the sorption reaction. By using two kinetic models-pseudo-first order-PFO(4) and pseudo-second order-PSO (5) linear forms were applied of the studied of the adsorption kinetics of Dox systems (Figure 7):

\[
\ln \left( \frac{Q_e - Q_t}{Q_e} \right) = \ln Q_e - K_L t
\]

\[
\frac{t}{Q_t} = \frac{1}{K_L Q_e^2} + \frac{t}{Q_e}
\]

Where, $Q_e$ is the adsorption capacity of antibiotics at the equilibrium state and $Q_t$ is adsorption capacity of antibiotics at time of $t$; the PFO and PSO adsorption modulus are $K_L$ (1/min) and $K_S$ (g/mg×min), respectively.
The R² correlation coefficient was 0.966 of the PSO model for Chs based hydrogels, and this data indicates the adequacy of this fitting model. The meaning of this finding is that the adsorption of Dox by Chs based hydrogel is assumed to be kinetically controlled as a SO reaction and the adsorption is dependent on the dose of natural based hydrogel and concentrations of Dox molecules. According to the PSO rate constant data the chemical adsorption mechanism involves electrostatic mutual attraction for AG and GA graft copolymer based hydrogel.

Thermodynamic parameter is necessary to determine the spontaneity or otherwise of an adsorption process. ΔGº-Gibbs free energy, ΔHº-enthalpy, ΔSº-entropy change, etc., are important useful thermodynamic parameters. These first three parameters are critically important for predicting adsorption mechanisms and thermodynamics, for the characterization and optimization of an adsorption process. The basic ΔGº, ΔHº, and ΔSº thermodynamic parameters were evaluated by (6)–(8) equations.

\[
\Delta G = -RT \ln K \quad \text{(6)}
\]
\[
\ln K = \frac{\Delta S}{R} - \frac{\Delta H}{RT} \quad \text{(7)}
\]
\[
\Delta G^0 = \Delta H^0 - T \Delta S^0 \quad \text{(8)}
\]

Where, K are Langmuir and Freundlich isotherm constant, L/mol; R = 8.314 J/mol×K is the universal gas constant. The plot of lnK values against 1/T, will give ΔHº, and ΔSº as the incline and intercept, respectively. The typical thermodynamic values for Dox adsorption onto different hydrogel are shown in Tables 2. Effect of temperature of adsorption process were conducted at 283, 293, 303 and 313 K in 3 h and determined the following thermodynamic parameters.

**Table 3: Thermodynamic parameter of Dox by natural based graft copolymer hydrogel**

Table 2 showed that Dox adsorption onto different natural based hydrogels was predominantly an endothermic process. The endothermic nature of the sorption process suggests the possibility of multiple displacements of solvent molecules sequel to Dox adsorption onto the hydrogel surfaces and volume pores. Table 2 showed that the Dox adsorption was mostly physical (0<ΔHº<20 KJ/mol),
except for few studies that are predominated by physical-chemical adsorption. A positive $\Delta S^\circ$-value implies high hydrogel-Dox affinity during adsorption. Known that, pH medium changes the charges of hydrogel surfaces and drug molecules. From the Fig. 8 showed that at pH lower than the isoelectric point, hydrogels are positively charged. The pH higher from the isoelectric point gels in a negatively charged. The adsorption of Dox molecules occurs on the top layer phase of the hydrogel surface based on the surface potential data.

**CONCLUSION**

The specific chemical and physical sorption mechanism of doxycycline antibiotic adsorption onto Chs, AG and GA based hydrogels were thoroughly investigated. The isothermic values are well fitted by the Freundlich model for all experiments. Kinetic experiments showed that sorption data were best described by the pseudo-second order model. Adsorption process at different pH medium data’s confirmed that the sorption of antibiotic from medium by Chs, AG and GA based gels could be occurred by positive-negative charge interactions. This repulsion interaction occurred in the aromatic cycles and charged functional groups between the hydrogel and doxycycline. According to the data of the $\Delta G^\circ$ energy the sorption process is spontaneous. Finally, the study showed that Chs-graft-VPr-co-4VP is capable of removal of doxycycline antibiotic from the aqueous solution (85-88%) at the optimized conditions and these matrices can be used as potential drug delivery in biotechnology.
